ABSTRACT

DOI: https://doi.org/10.25241/stomaeduj.2019.6(4).art.3

Introduction: Recurrent aphthous stomatitis (RAS) is one of the most usual inflammatory diseases of the oral mucosa. The clinical characteristics of RAS are well defined, but the exact etiology and pathogenesis of the disease are not. Several investigations have noticed cigarette smoking to have a protective effect on RAS. The aim of the study is to investigate the association between cigarette smoking and RAS in order to improve the current knowledge on this issue.

Methodology: 68 patients with RAS participated in the study. A full mouth clinical examination was performed and a medical history was taken for each patient. A statistical analysis was performed.

Results: While 6 (8.9%) of patients with RAS were smokers, a significantly higher percentage (24.9%) among the subjects with RAS were not smokers (group II).

Conclusion: The negative association between smoking and RAS indicated by this investigation is not meant to encourage people to smoke nor to spare them from the intention to quit their habit. These conclusions should be used to clear up the cause and pathogenesis of the RAS and to identify better prevention and treatment.

Keywords: Oral Medicine; Aphthae; Recurrent Aphthous Stomatitis; Mouth; Smoking.

1. Introduction

Recurrent aphthous stomatitis (RAS) is a very common disease of the oral mucosa. It is called minor aphthous ulcers, herpetiform ulcers, aphthosis and many other names. Aphthous ulcers can occur alone or as part of a syndrome [1]. RAS occurs only in non-keratinized mucosa as painful, shallow round ulcers with an erythematous halo covered by a membranous layer. The clinical ulcerative period for minor aphthous ulcers may last for 2 weeks and lesions usually heal without a scar [2]. The clinical characteristics of RAS are well known, but the exact etiology and patho-genesis of the disease are not complete. The etiology of RAS includes stress, microorganisms, food hyper-sensitivity, immune dysregulation, hormonal fac-tors and a genetic predisposition, usage of the toothpaste with sodium lauryl sulfate (SLS) [1,2]. Current investigations have focused on a possible immunopathogenesis of RAS [2,3]. The epithelial cell death and the creation of ulceration probably results from the activation of a cell-mediated immune response in which Tumor Necrosis Factor Alpha (TNFα) and other cytokines are produced [3]. Inheritance of HLA-B51 antigen, vitamin B12 deficiency, recurrent herpes labialis, Helicobacter pylori, hepatitis C and hypersensitivity to nickel are involved in the development of RAS [4,5]. It is necessary to better understand the pathogenesis and primary cause of RAS [2]. Previously, it is thought that approximately 0.89% of the adults over 17 years of age have at least one aphthous lesion and that males (1.13%) have almost twice the RAS than females (0.67%). It is noticed that reported prevalence of RAS varies according to patient selection, presence of lesions at the time of investigation or during a specified period and newer literature data show that the RAS prevalence is between 5 and 60%, depending on the population group studied [2]. It is estimated that tobacco use is the major cause of more than 5 million deaths every year [6]. Smoking is a common risk factor in a number of chronic diseases like lung diseases, cancer, cardiovascular diseases; and a major risk factor in the prevalence of
periodontal diseases [6-10]. Cigarette smoke contains approximately 4800 chemicals, with over 60 of them known to have damaging effects on human cells [11]. Cigarette smoking could camouflage signs of periodontal disease like gingival bleeding or redness, by suppressing the immune response which could cause a problem in the diagnosis of the disease. Several studies have noticed cigarette smoking to have a protective effect on RAS [12-15]. It is not clear how cigarette smoking can reduce RAS prevalence but it is thought that immunological mechanisms are involved and that the cytokine (TNF) plays an important role in the pathogenesis. Nicotine has been shown to influence the immune response in inflammatory conditions [16,17]. It acts through the central nervous system inducing the production of glucocorticoids and activating the autonomic nervous system and consequently reducing the level of inflammation [16]. Nicotine can activate the nicotinic acetylcholine receptors on macrophages and reduce the production of TNF1 and interleukins [17].

2. The aim of the study
The aim of the study is to investigate the association between cigarette smoking and RAS in order to increase current knowledge on this issue.

3. Methodology
The study was conducted on 338 patients who came at the Department of Oral Medicine and Periodontology of the Dental Clinic of Faculty of Medicine, Niš University, for one year. The Ethics Committee of the Faculty of Medicine Niš approved the study protocol (evidential number 01-2800-7). After the medical history was taken, the patients who had undergone antibiotic and corticosteroid therapy in the last three months, were not included in the study. A full mouth clinical examination was performed and the patients with active aphthous lesions and who per medical history had suffered from oral ulcers at least once within a period of 5 months were considered to suffer from RAS. The patients with other oral diseases who came at the Dental Clinic of the Medical Faculty Niš for other medical reasons were also included in this study. Out of all the examined patients, 68 patients had RAS and 270 had no RAS or RAS history. Patients who smoked over 10 cigarettes per day (per medical history) were considered to be “smokers” and they constituted group I (74 patients). The nonsmoking patients constituted group II (264 patients).

4. Results
There were 68 participants with RAS, out of which 31 (46.92%) were men and 37 (53.1%) were women. The average age was 29.7± 8.8 years. 66 (97.1%) had the minor type of the disease, 2 (2.9%) had both minor and major RAS. The relationship between RAS and smoking is shown in Table 1. While 6 (8.9%) of patients with RAS were active smokers (group I), a significantly higher percentage (24.9%) among the subjects with RAS were not smokers (group II) (χ² =70.4; d. f. = 2, P < 0.001).

5. Discussion
Smoking is a known risk factor in a number of chronic diseases and major risk factor of periodontal disease [2-6]. Cigarette smoking suppresses the immune host response, masks early signs of periodontal disease and has as reported by some authors a beneficial protective effect on RAS. It has also been noticed that the incidence of RAS is higher among young individuals and that adults younger than 40 years of age have more than twice higher RAS rate than those older than 40 years [12-15]. We noticed similar results in our study where the average age of the patients with RAS was 29.7±8.8 years. It could be suspected that stress could be an aphthae provoking factor. Previously, lifestyle could induce stress and social conditions and self-management are important determinants of health. The effects of living exposed to many stress factors may cause poorer health and more frequent occurrence of RAS [18,19]. Literature data reveal a significant reduction of RAS in individuals who smoke. The prevalence and odds ratios for number of cigarettes smoked is significant and suggest a dose response effect [14,15]. A reduction in RAS prevalence with higher blood levels of nicotine is found to be significant [20]. Our study noticed a similar situation. where 8.9% of patients with RAS were active smokers and a significantly higher percentage (24.9%) among the subjects with RAS were not smokers (group II) (χ² =70.4; d. f. = 2, P < 0.001). Kalpana [13] noticed that significant differences exist in the prevalence of RAS among cigarette smokers, which could be related to the number of cigarettes smoked per day and duration of the habit. The “protective effect” on

Table 1. Relationship between RAS and smoking.
RAS was noticed only when the persons were heavy smokers or had smoked for longer periods of time. Cigarette non-smokers have far greater odds of RAS than individuals who smoked >1 pack per day. It could was concluded that the associations of RAS with cigarette smoking and with cotinine levels were significant. Our study noticed similar results, namely that a higher number of individuals with RAS were nonsmokers (24.9%). RAS is characterized by recurrences of short-lived lesions. The lesions are not always noticed at the time of examination and the diagnosis is often based on the patient’s clinical history. The statistical evaluation of RAS is hampered because lesions cannot be evaluated by the investigator at any time and is usually based on a self-reported history of RAS. Such a diagnosis is less reliable that one based upon the observation of present lesions by a practitioner. It is to be noticed that many of the studies which found a negative correlation between RAS and smoking were based on a self-reported history of RAS [21]. Information should be carefully interpreted, especially where there is some basis to suspect response bias. The findings in this study were based on anamnesis and clinical examination conducted by an experienced practitioner and provide data on the general prevalence of RAS in smokers. There is a small number of studies in which patients were diagnosed by direct detection of present lesions by a practitioner. Queiroz et al [22] evaluated 4895 cases of recurrent aphthous ulcersations with a focus on treatment, diagnosis and etiology. Data such as sex, age, race, location, smoking habits, types of treatment, relapsing episodes, laboratory test results and clinical characteristics were collected. Regarding smoking habits, in the majority of patients, 59 (77.6%) smoking was not recorded. The investigators did not consider the percentages of smoking notifications because they are influenced by a bias of selection of the sample. Other researchers have found a lower incidence of RAS in smokers on the basis of the disease history but not by direct detection of present lesions by a practitioner [12-14]. A similar negative correlation between smoking and RAS was noticed in our study. The treatment and, many times, the diagnosis of RAS are a challenge in the daily life of the clinician. Dental professionals and otorhinolaryngologists are usually responsible for the first contact with the patients who have RAS. These professionals should be alert to the clinical aspects of this condition since each patient will be treated in an individualized manner, because treatment is usually palliative and not curative.

6. Conclusion
On the basis of the aim of the study, its applied methodology and the results obtained it can be concluded that the incidence of RAS is higher among young individuals and among subjects who do not smoke. The negative association between smoking and RAS in our study is not indeed meant to encourage people to smoke nor to sway them in the decision to quit their habit. Smoking cessation is the main option to remove the harmful tobacco effects on oral tissues and to improve the quality of life.

Questions

1. Recurrent aphthous stomatitis (RAS) is very common disease of the oral mucosa. It is called:
   q. a. Minor aphthous ulcers;
   q. b. Herpetiform ulcers;
   q. c. Simple aphthosis;
   q. d. All of the above answers are correct.

2. Cigarette smoking could influence signs of periodontal disease like:
   q. a. Provoking bleeding;
   q. b. Provoking gingival redness;
   q. c. Camouflage gingival bleeding or redness;
   q. d. Provoking gingival swelling.

3. The etiology of RAS includes:
   q. a. Stress and immune dysregulation;
   q. b. Microorganisms and food hypersensitivity;
   q. c. Hormonal factors and a genetic predisposition;
   q. d. All of the above answers are correct.

4. The patients were divided into:
   q. a. Two groups: smokers and nonsmoking patients;
   q. b. Three groups: smokers, nonsmoking patients and patients with RAS;
   q. c. Two groups: smokers and patients with RAS;
   q. d. Two groups: nonsmoking patients and patients with RAS.
